Models in Testing

- Model checking is based on models of the artifact, testing addresses the artifact
- However, some modeling is often required also for testing
 - models for the environment (i.e., what is providing inputs)
 - models for plant, when the software is a controller
 - in some cases, testing on the final product in its “natural” environment only may be also dangerous
 - e.g., testing of the controller for a flying aircraft
 - models of the software itself
 - UML diagrams
 - control flow diagrams et al. (will be defined in the following)
 - help in devising better tests
- May be already available from specifications, or a modeling phase may be needed

Models Must Be...

- Compact, i.e., understandable
 - often, they are for human inspection
 - if models are for some automatic procedure, then they must be manipulable in the given computational resources
 - this is exactly the case for model checking!
- Predictive, i.e., not too simple
 - at least be able to detect what is “bad” and what is “good”
 - different models may be used for the same artifact, when testing different aspects
 - e.g., model to predict airflow w.r.t. efficient passenger loading and safe emergency exit

DISIM
Dipartimento di Ingegneria
e Scienze dell'Informazione
e Matematica

Models Must Be...

- Semantically meaningful
 - given something went bad, we need to understand why
 - identify the part with the failure
- Sufficiently general
 - not too specilized on some characteristics
 - otherwise, not useful
 - e.g., a C program analyzer which only works for programs without pointers

Finite Abstraction of Behaviour

- Given a program, a state is an assignment for all variables in the program
 - state space*: set of all possible states
- A behaviour is a sequence of states, interleaved by program statements being executed
- The number of behaviours for non-trivial programs is extremely huge
 - infinite if we do not consider machine limitations
 - e.g., integers need not to be represented on maximum 64 bits
- An *abstraction* is a function from states to (reduced) states
 - some detail are suppressed
 - e.g., some variables are not considered

UNIVERSITÀ
DEGLI STUDI
DELL'AQUILA

DISIM
Dipartimento di Ingegneria
e Scienze dell'Informazione
e Matematica

Finite Abstraction of Behaviour

- Two different states may be considered the same by an abstraction
 - e.g., they differ by some variable, which is abstracted out
- States sequence may be squeezed
- Non-determinism may be introduced
 - e.g., a choice was made by considering the value of some abstracted-out variable
- In model checking, this is done by hand for each system
 - here, instead, we will consider some standard models which are especially tailored for testing
 - in some cases, they may be automatically extracted from code

Finite Abstraction of Behaviour

(Intraprocedural) Control Flow Graphs

- Model close to the actual program source code
 - finite by construction
- Often compilers are also able to build the control flow graph
 - e.g., `gcc -fdump-tree-cfg`
- Directed graph:
 - nodes are program statements or group of statements
 - more on this in the following
 - edges represent the possibility to go from a node to another
 - either by branch or by sequential execution

UNIVERSITÀ
DEGLI STUDI
DELL'AQUILA

DISIM
Dipartimento di Ingegneria
e Scienze dell'Informazione
e Matematica

Control Flow Graphs (CFGs)

- Nodes usually are a maximal group of statements with a single entry and single exit
 - *basic block*
 - e.g., sequential assignments are grouped together
- On the contrary, it may happen that a single statement is broken down
 - e.g., `if (++i > 3)` becomes `i++`; `if (i > 3)`
 - e.g., the `for` statement
 - e.g., short-circuit evaluation
 - it depends on the level of accuracy needed

Control Flow Graphs

Control Flow Graphs

- Let P be a (part of a) function or procedure for which testing must be performed
 - white-box testing: we know the code of P as a sequence $\mathcal{C}(P) = \langle I_1, \dots, I_k \rangle$ of statements
 - we assume P is written in some imperative language
 - we assume that complex statements in $\mathcal{C}(P)$ are already broken down in parts
 - short-circuited conditions, inline increments, function/procedure calls...
- Let $g = \langle i_1, \dots, i_m \rangle$ be a grouping for the statements of $\mathcal{C}(P)$
 - $1 \leq i_j < i_{j+1} \leq k$ for all $j = 1, \dots, m - 1$
 - e.g., for $g = \langle 3, 5, 10 \rangle$ we will consider three blocks:
 - the first 3 statements, then other two statements, and finally the remaining 5 statements
 - we will call g *granularity* for a given $\mathcal{C}(P)$

Control Flow Graphs

- A CFG for a program P with granularity g is a graph $G = (V, E)$ s.t.
 - $V = \{\langle I_{g_{i-1}+1} \dots I_{g_i} \rangle \mid i = 1, \dots, |g|\}$
 - with $g_0 = 0$
 - nodes are basic blocks and $|V| = |g|$
 - $E = \{(u, v) \mid u, v \in V \wedge \text{control flow from last statement of } u \text{ and first of } v \text{ may take place}\}$
- Typically, nodes $v_i \in V$ are labeled with the corresponding basic block $\langle I_{g_{i-1}+1} \dots I_{g_i} \rangle$
- Typically, edges $(u, v) \in E$ may be labeled by a boolean value if flow from u to v is conditioned
 - last statement of u is an if or a while
 - and similar, e.g., for, until etc
- In some cases, some alphanumeric label is added to ease references

From CFG to LCSAJ

- Linear code sequences and jumps
 - maximal sequences of consecutive statements
 - may be directly derived from a CFG
 - very useful for testing coverage criteria
- Let $G = (V, E, L_1, L_2)$ be a labeled CFG
 - $L_1 : V \rightarrow \mathcal{L}_V, L_2 : E \rightarrow \mathcal{L}_E$ are two labeling functions for nodes (basic blocks) and edges, respectively
- The LCSAJ associated to G is
$$\mathcal{I}(G) \subseteq \{ \langle l_1, l_2, l_3 \rangle \mid l_1, l_3 \in \mathcal{L}_E, l_2 \in \mathcal{L}_V^* \} \text{ s.t.:}$$
 - l_1 is connected to the first statement of l_2
 - l_3 is connected from the last statement of l_2
 - l_2 only contain consecutive statements in $\mathcal{C}(P)$

Control Flow Graphs

```
1  /**
2   * Remove/collapse multiple newline characters.
3   *
4   * @param String string to collapse newlines in.
5   * @return String
6   */
7  public static String collapseNewlines(String argStr)
8  {
9      char last = argStr.charAt(0);
10     StringBuffer argBuf = new StringBuffer();
11
12     for (int cldx = 0 ; cldx < argStr.length(); cldx++)
13     {
14         char ch = argStr.charAt(cldx);
15         if (ch != '\n' || last != '\n')
16         {
17             argBuf.append(ch);
18             last = ch;
19         }
20     }
21
22     return argBuf.toString();
23 }
```

Call Graphs

- CFG is typically intraprocedural; call graphs are interprocedural
 - simply a graph where nodes are defined functions
 - there is an edge from f to g iff f *may* call g
 - thus, they may contain calls which are actually never made
 - sometimes arguments are made explicit
 - number of paths inside a call graph may be exponential, even without recursion

Mealy Machine Formal Definition

- A Mealy machine is a 6-tuple $\mathcal{M} = (S, S_0, \Sigma, \Lambda, T, G)$ consisting of the following:
 - a finite set of states S
 - a start state (also called initial state) $S_0 \in S$
 - a finite set called the input alphabet Σ
 - a finite set called the output alphabet Λ
 - a (deterministic!) transition function $T : S \times \Sigma \rightarrow S$ mapping pairs of a state and an input symbol to the corresponding next state
 - an output function $G : S \times \Sigma \rightarrow \Lambda$ mapping pairs of a state and an input symbol to the corresponding output symbol.
- Given an input $w \in \Sigma^*$, \mathcal{M} outputs $o \in \Lambda^*$, $|o| = |w|$ s.t.
 - $\forall i = 1, \dots, |w|. s_i = T(s_{i-1}, w_i) \wedge o_i = G(s_{i-1}, w_i)$
 - $s_0 = S_0$

Data Flow Models

- CFGs, FSMs etc are a good way to represent *control flow*
- What about *data flow*?
- Again, ideas are borrowed from compilers theory
 - data flow is used to detect errors for type checking, or also opportunities for optimization
 - also used in software engineering tout court, for refactoring or reverse engineering
- As for testing, useful for:
 - select test cases based on dependence information
 - detect anomalous patterns that indicate probable programming errors, e.g. usage of uninitialized values

Definition-Use Pairs

- Definition of a variable: either its declaration or a write access
 - for languages like Python, only write access...
 - write access may be:
 - left part of an assignment
 - parameter initialization in function calls
 - other special cases such as ++ construct in C-like languages
- Use of a variable: a read access
 - right part of an assignment
 - variable passed in function calls
 - variable used without being modified
- The same line of code may be both definition and use
 - typically, nearly all lines either define and/or use at least one variable

Definition-Use Pairs

- For a given definition, there may be many uses, and viceversa
 - of course, for a fixed variable
- A definition-use pair combines a given use with the *closest* definition
 - w.r.t. some possible execution (*path*) of the code
- Other definitions behind the closest one are *killed*

UNIVERSITÀ
DEGLI STUDI
DELL'AQUILA

DISIM
Dipartimento di Ingegneria
e Scienze dell'Informazione

Definition-Use Pairs

- Consider an execution path $\pi = s_1, \dots, s_k$:
 - s_i are *statements* and s_i, s_{i+1} may be contiguous in π iff the control flow may go from s_i to s_{i+1}
 - e.g., from the previous code: 1,2,3,8,9 and 1,2,3,4,5,6,7,3,4,5,6,7,8,9
- Consider an execution path $\pi = s_1, \dots, s_k$:
 - if $\exists k. \text{use}(v) \in s_k$, let $L = \{\ell < k \mid \text{def}(v) \in s_\ell\}$
 - $(d, u) = (\max L, k)$ is a definition-use pair
 - v_d reaches u or v_d is a *reaching definition* of u
 - s_ℓ is a *killed definition* if $\ell \in L \wedge \ell \neq \max L$
 - the sub-path $s_\ell \dots s_k$ is *definition-clear*

Definition-Use Pairs

Control Dependence

- *Control dependence graph*
 - nodes are statements, but again granularity may change
 - to define edges, the notion of *dominators* is needed
 - a node n is dominated by node m iff, for all paths π from the root to n , m is also in π
 - the (unique) *immediate dominator* of n is the closest dominator of n
 - i.e., with the minimum path to reach n
 - also stated as: the dominator of n which does not dominate any other dominator of n
 - *dominator tree*: there is an edge (s, t) iff s is the immediate dominator of t
 - for all reachable nodes there is exactly one immediate dominator
 - *post-dominators*: same definition, but in the reverse graph
 - an exit node must be present

Dominators

Control Dependence

- Back to the control dependence graph: given nodes s, t , we have that (s, t) is an edge iff t is *control dependent* on s
- To define when t is control dependent on s , the following holds:
 - t is reached on all execution paths
 - then, t is control dependent on the root only
 - it may actually be the root itself
 - t is reached on some but not all execution paths; then for s the following must hold:
 - the outgoing degree of s in the CFG is at least 2
 - one of the successors of s in the CFG is post-dominated by t
 - s is not post-dominated by t

Control Dependence

Full control graph

Available Expressions

- Other uses of the control flow graph: available expressions
 - again, mutated from compilers: when a given expression can be evaluated just once and stored for later use
- An expression E is:
 - *generated* when its value is computed
 - *killed* when at least one of the variables involved changes its value
 - not necessarily by assignments, could be a side effect of a function call...
 - *available* at some point p iff, for paths π from start to p , E is generated but not killed in π
- Algorithm is very similar to the reaching definitions algorithm:
 - for available expressions, is a forward all-paths analysis
 - for reaching definitions, is a forward any-path analysis

Algorithm to Generate All Available Expressions

Algorithm *Available expressions*

Input: A control flow graph $G = (\text{nodes}, \text{edges})$, with a distinguished root node *start*.

$\text{pred}(n) = \{m \in \text{nodes} \mid (m, n) \in \text{edges}\}$

$\text{succ}(m) = \{n \in \text{nodes} \mid (m, n) \in \text{edges}\}$

$\text{gen}(n)$ = all expressions e computed at node n

$\text{kill}(n)$ = expressions e computed anywhere, whose value is changed at n ;

$\text{kill}(\text{start})$ is the set of all e .

Output: $\text{Avail}(n)$ = the available expressions at node n

for $n \in \text{nodes}$ **loop**

$\text{AvailOut}(n)$ = set of all e defined anywhere ;

end loop;

$\text{workList} = \text{nodes}$;

while ($\text{workList} \neq \{\}$) **loop**

// Take a node from worklist (e.g., pop from stack or queue)

n = any node in workList ;

$\text{workList} = \text{workList} \setminus \{n\}$;

$\text{oldVal} = \text{AvailOut}(n)$;

// Apply flow equations, propagating values from predecessors

$\text{Avail}(n) = \bigcap_{m \in \text{pred}(n)} \text{AvailOut}(m)$;

$\text{AvailOut}(n) = (\text{Avail}(n) \setminus \text{kill}(n)) \cup \text{gen}(n)$;

if ($\text{AvailOut}(n) \neq \text{oldVal}$) **then**

// Propagate changes to successors

$\text{workList} = \text{workList} \cup \text{succ}(n)$

end if;

end loop;

From Available Expressions to General Properties

- G occurs on all execution paths leading to U , and there is no intervening occurrence of K between the last occurrence of G and U
- For any G, K, U , we can use the algorithm above
- E.g., it can be used for the Java initialized variables problem
 - before any use, a variable must be initialized
 - the kill set is not empty only in the starting node, as we cannot uninitialize a variable
 - also a warning in C

Example for Uninitialized Variables

```
static void questionable() {  
    int k;  
    for (int i=0; i < 10; ++i) {  
        if (someCondition(i)) {  
            k = 0;  
        } else {  
            k += i;  
        }  
    }  
    System.out.println(k);  
}
```

Example for Uninitialized Variables

Live Variables: Backward Analysis

- A variable v is *live* at point p iff, on some path π from p to the end, a read on v occurs before a write on v
 - `b = 5 /* b is live, c is not */; c = 3 /* now, both b and c are live */; a = f(b, c)`
- From the definition above, we need a backward-any path algorithm
- General property: after D occurs, there is at least one execution path on which G occurs with no intervening occurrence of K
- Example: useless definitions, i.e., assign a variable which is never used afterwards
 - important for languages where declarations are not used, e.g., Python and Perl
 - not an error, but probably the variable is misspelled

Example for Useless Variables

```
class SampleForm(FormData):  
    """ Used with Python cgi module  
        to hold and validate data  
        from HTML form """  
  
    fieldnames = ('name', 'email', 'comment')  
  
    # Trivial example of validation. The bug would be  
    # harder to see in a real validation method.  
    def validate(self):  
        valid = 1;  
        if self.name == " " : valid = 0  
        if self.email == " " : valid = 0  
        if self.comment == " " : valid = 0  
        return valid
```

Backward all-Paths Analysis

- Live variable analysis is a backward any-path analysis
- What about the missing one: backward all-paths analysis?
- After D occurs, G always occurs with no intervening occurrence of K
 - D inevitably leads to G before K
- Examples:
 - interrupts are re-enabled after interrupt routine is executed
 - files are closed on process termination
 - etc

Generalizing Data Flow Analysis

- The examples above “simulates” the execution of a piece of code, considering its CFG
- All possible executions are considered, but only a restricted info is kept
 - “summary state”
 - e.g., a bit to denote if a variable has been defined
 - actually having all executions with full information entails all possible values for variables are considered
- By considering different kinds of summary states, we have different types of analyses
 - example: “taint mode” in the Perl language
 - blocks some sensitive operations depending on variables defined outside the Perl script itself
 - opening a file is a sensitive operation
 - thus, e.g., you cannot define a variable v by reading some input and then open a file having v as a filename

Data Flow Analysis with Arrays and Pointers

- Easy to perform data flow analysis on single variables
- When considering pointers and/or arrays, many difficulties arise
- Difficulty 1: definition-use on an array referenced by variables
 - e.g.: `a[i] = 1; k = a[j];` is a definition-use pair iff `i == j`
 - too difficult to determine if such a condition is always true, always false, or sometimes true and sometimes false
- Difficulty 2: aliases obtained by full array assignment
 - e.g., `b = a; a[2] = 42; i = b[2];` is a definition-use pair (or triple?) in Java

Difficulty 3: Arguments Passing

```
fromCust == toCust? fromHome == fromWork? toHome ==  
toWork?
```

```
public void transfer (CustInfo fromCust, CustInfo toCust) {
```

```
    PhoneNum fromHome = fromCust.gethomePhone();
```

```
    PhoneNum fromWork = fromCust.getworkPhone();
```

```
    PhoneNum toHome = toCust.gethomePhone();
```

```
    PhoneNum toWork = toCust.getworkPhone();
```

Interprocedural Analysis

- Calls between different functions/methods, important, e.g., for the previous slide
- Simply following calls and returns in a CFG-like way is not practical: too many spurious paths
 - $(A, X, Y, B), (C, X, Y, D)$ are ok
 - $(A, X, Y, D), (C, X, Y, B)$ are impossible

Interprocedural Analysis

- To solve the problem, context is needed
 - if sub is called by A, it must return in B
- Number of contexts is exponential
 - may be ok for a small group of functions, e.g., a not-too-big single Java class
- Some special cases exist
 - the info needed to analyze the calling procedure must be small
 - e.g., proportional to the number of called procedures
 - the information about the called procedure must be context-independent
 - example: declaration of exception throwing in Java
